New directions in the retrospective diagnosis of leprosy by combining clinical and paleopathological data

VÍTOR MATOS [vmatos@antrop.uc.pt] | CIAS - Research Centre for Anthropology and Health | Department of Life Sciences, University of Coimbra, Portugal

Introduction

The first paleopathological criteria for the diagnosis of leprosy were presented 65 years ago, at the VI International Leprosy Congress in Madrid, by the Danish physician V. Møller-Christensen (1953, 1967), who defined facies leprous. Later this concept evolved to a new one, the rhinomaxillary syndrome (RS) that became central to the retrospective diagnosis of leprosy until the present. The rhinomaxillary syndrome was proposed by Andersen and Manchester (1992: 122) who considered that “the presence of all components of the rhinomaxillary syndrome is pathognomonic of lepromatous or near-lepromatous leprosy”. Lepromatous (LL) and tuberculoid (TL) leprosy are the two clinical polar forms of leprosy according to the Ridley and Jopling (1966) classification. During the last six decades facies leprous, RS, and apendicular destructive bone changes (Figure 1), have been widely used (Otte, 2003), and sometimes misused, to characterize the chronological and geographic distribution of leprosy. Surprisingly, a review of published paleopathological leprosy cases shows that TL is almost absent in the bioarchaeological record. This gap must be addressed in order to improve our knowledge regarding the origin and paleoepidemiology of leprosy. This study aimed to collect and correlate clinical and paleopathological data on leprosy related bone changes in order to answer the following:

Do LL and TL present distinct patterns of bone involvement?

Can TL be diagnosed in archaeological skeletal material?

Results and Discussion

1. Medical archives - Leprosarium Hospital-Colónia Rovisco Pais (HCRP), Tocha, Portugal

300 clinical files randomly selected (details in Matos, 2009):
- 150 files from each type of leprosy (LL and TL);
- 150 from each sex;
- 35 (11.9%) non adults and 258 adults (88.1%).
First admission: 4 to 93 years old (median: 37: s.d.: 17.6).
Only bone changes before antibiotic therapy were collected.

2. St. Jørgen’s medieval leprosarium skeletons (13th – 16/17th cent.), Odense, Denmark

191 skeletons, housed at the University of Southern Denmark, at Odense, with well preserved rhinomaxillary area were observed (details in Matos, 2009):
- 148 adults (77.5%) and 43 non adults (22.5%);
- 75 males, 63 females and 37 undetermined.
Standard osteological and paleopathological methods were applied.

Samples and Methods

1. HCRP leprosy patients

Overall prevalence of osseous lesions: 13.0% (39/300).

Observed bone involvement patterns:

LL: (4.0% [6/150]): Nasal destruction with or without hand and foot bone lesions.

LT (22.0% [33/150]): No nasal destruction and hands/feet bone lesions present.

Bone changes more prevalent in TL than in LL patients (OR=8.18; IC95%=1.69, 39.65; x2=12.5 [p<0.001]).

• The paleopathological identification of TL should be considered when an adult skeleton without rhinomaxillary lesions presents acroosteolysis and destructive remodeling/concentric atrophy of hand and/or feet bones, and after the exclusion of other pathological conditions that must be considered on the differential diagnosis of these lesions; for example, diabetes, frostbite, psoriatic arthritis, Raynaud’s syndrome, etc.

• The long time to affect the skeleton after the disease onset and the poor post mortem preservation of small and fragile bones, such as those from the nasal area, may be responsible for the few leprosy cases identified on human osteological remains, specially in relation to what would be expected from documentary sources.

• Further investigations are necessary concerning the retrospective diagnosis of leprosy. The knowledge on how the various forms of leprosy affected humankind would help a better understanding of leprosy evolution and history.
